^aDepartment of Physics, University of Washington, Seattle, WA 98195–1560

We review the construction and basic properties of a three-dimensional effective field theory for high-temperature SU(3) Yang-Mills theory, which respects its center symmetry and was introduced in Ref. [1]. We explain why the phase diagram of the new theory is expected to closely resemble the one of the full theory and argue that this implies that it is applicable down to considerably lower temperatures than the usual non-Z(3)-symmetric 3d effective theory EQCD.

1. INTRODUCTION

Recent years have witnessed significant progress being made in the study of equilibrium thermodynamics of high-temperature QCD on two fronts. On one hand, the lattice QCD community, equipped with ever-improving computational resources, has produced an abundance of new numerical results that are valid in the region near the deconfinement temperature T_c . At asymptotically high T , a number of high-order perturbative calculations have on the other hand been carried out [2], in which a vital tool has turned out to be the use of dimensionally reduced effective theories EQCD and MQCD that correctly describe the behavior of static observables in the original theory at sufficiently large length scales [3]. The construction of these theories relies only upon the existence of a hierarchy between the hard, soft and ultrasoft scales, $2\pi T \gg m_D \gg m_{\text{mag}}$, where m_D stands for the electric Debye mass and m_{mag} for the magnetic mass, which is known to hold true at asymptotically high temperatures and in addition at least to a limited extent all the way down to T_c . Simulations in EQCD have, however, shown that this theory fails to reproduce the dynamics of the full one in the vicinity of the transition region and, in particular, that its phase diagram has a highly unphysical structure.

At least in the case of pure Yang-Mills theory, *i.e.* $N_f = 0$ QCD, the unphysical properties of EQCD at temperatures $T \sim T_c$ can to a large extent be attributed to its failure to respect all the symmetries of the underlying theory, one of the most fundamental tenets of effective theory building. The Yang-Mills theory has namely a global Z(3) symmetry related to the invariance of its action under gauge transformations with twisted boundary conditions in the temporal direction, which the effective theory does not possess. On the contrary, the leading order Lagrangian of EQCD can be obtained by expanding the one-loop effective potential of the Wilson line $\Omega(\mathbf{x})$ in the full theory around one of its three degenerate Z(3)-minima, which is a valid prescription only in the close vicinity of this minimum. Thus, EQCD does not possess the true vacuum structure of the full theory

*vuorinen@phys.washington.edu

and therefore cannot correctly describe its dynamics near the deconfinement transition, which is known to be of weakly first order and driven by tunnelings between the three deconfined $Z(3)$ -vacua.

As a step towards obtaining an effective description of finite-temperature $SU(3)$ Yang-Mills theory that provides a smooth interpolation between the phase transition region and asymptotically high temperatures, it was proposed in Ref. [1] that one should construct a three-dimensional effective theory that respects the $Z(3)$ symmetry, but on the other hand reduces to EQCD at high enough T . While reproducing all perturbative predictions obtained through EQCD, this theory would automatically capture also the dynamics of thermal fluctuations that create bubbles sampling all three $Z(3)$ -phases. It should thus have a phase structure similar to that of the full four-dimensional theory, containing *e.g.* a quadruple point, where the deconfined phases coexist with the confining one. In particular, the new theory should provide a valid description of the full theory on a temperature range much wider than what EQCD is capable of.

In the present paper, we will briefly review the perturbative construction of a $Z(3)$ -symmetric effective theory that was first presented in Ref. [1]. We will also outline the non-perturbative simulations that need to be carried out in order to match the last undetermined parameters of the effective theory to the full one.

2. $Z(3)$ INVARIANT EFFECTIVE THEORY

The minimal set of degrees of freedom in a three-dimensional $Z(3)$ invariant effective theory for quarkless QCD consists of the spatial gauge field $\mathbf{A}(\mathbf{x})$ and the Wilson line $\Omega(\mathbf{x})$. However, due to the unitarity of $\Omega(\mathbf{x})$ and our desire to obtain a perturbatively renormalizable theory with a polynomial Lagrangian, we choose to instead work with an unconstrained 3×3 complex matrix $\mathcal{Z}(\mathbf{x})$, in which the extra degrees of freedom will be chosen massive enough so that they effectively decouple from the physics of length scales $1/(gT)$ and higher. The relation between the full theory (and the effective actions that have been built for $\Omega(\mathbf{x})$ near T_c [4–6]) and the new effective theory should be viewed as analogous to the relation between non-linear and linear sigma models or between the Ising model and a double-well ϕ^4 field theory.

We require that the effective theory Lagrangian be invariant under three-dimensional $SU(3)$ gauge transformations as well as global $Z(3)$ phase rotations, and choose it to be composed of standard derivative terms for $\mathbf{A}$ and $\mathcal{Z}$ plus a potential for the complex scalar $\mathcal{Z}$,

$$\mathcal{L} = g_3^{-2} \left\{ \frac{1}{2} \text{tr} F_{ij}^2 + \text{tr} (D_i \mathcal{Z}^\dagger D_i \mathcal{Z}) + V(\mathcal{Z}) \right\}, \quad (1)$$

with $D_i \equiv \partial_i - i[A_i, \cdot]$ and $F_{ij} \equiv \partial_i A_j - \partial_j A_i - [A_i, A_j]$. Defining

$$L(\mathbf{x}) \equiv \text{tr} \mathcal{Z}(\mathbf{x}), \quad M(\mathbf{x}) \equiv \mathcal{Z}(\mathbf{x}) - \frac{1}{3} \text{tr} \mathcal{Z}(\mathbf{x}) \mathbf{1}, \quad (2)$$

the $Z(3)$ invariant potential $V(\mathcal{Z})$ will consist of two pieces,

$$V(\mathcal{Z}) = V_0(\mathcal{Z}) + g_3^2 V_1(\mathcal{Z}), \quad (3)$$

with

$$V_0(\mathcal{Z}) = c_1 \text{tr} [\mathcal{Z}^\dagger \mathcal{Z}] + c_2 (\det[\mathcal{Z}] + \det[\mathcal{Z}^\dagger]) + c_3 \text{tr} [(\mathcal{Z}^\dagger \mathcal{Z})^2], \quad (4)$$

$$V_1(\mathcal{Z}) = \tilde{c}_1 \text{tr} [M^\dagger M] + \tilde{c}_2 (\text{tr} [M^3] + \text{tr} [(M^\dagger)^3]) + \tilde{c}_3 \text{tr} [(M^\dagger M)^2]. \quad (5)$$

The first of these is referred to as the “hard potential” and the second as the “soft potential”, since at high temperatures and small g_3^2/T , $V_0(\mathcal{Z})$ will give the heavy excitations their $\mathcal{O}(T)$ masses, while $g_3^2 V_1(\mathcal{Z})$ will be responsible for the $\mathcal{O}(gT)$ masses of the physical components of $\mathcal{Z}$. The theory is a superrenormalizable, as the only renormalizations required (in addition to vacuum energy subtraction) are one- and two-loop adjustments of the coefficients c_1 and $\tilde{c}_1$ of the quadratic terms.

The above choices for the potentials are such that for $c_2 < 0$ and $c_2^2 > 9c_1c_3$, V_0 is minimized by an arbitrary $SU(3)$ matrix times $v/3$, with

$$v \equiv \frac{3}{4} \left(\frac{-c_2 + \sqrt{c_2^2 - 8c_1c_3}}{c_3} \right), \quad (6)$$

while for $\tilde{c}_3 > 0$ and $\tilde{c}_1\tilde{c}_3 > \tilde{c}_2^2$, V_1 is minimized by $M = 0$. Thus, with these parameter values the entire potential V is minimized by $\mathcal{Z} = \frac{v}{3} e^{2\pi i n/3} \mathbf{1}$, with $n \in \{0, 1, 2\}$, corresponding to the three $Z(3)$ minima of the effective potential for Ω in the full theory. While the form of V_0 was dictated by computational convenience (see Ref. [1]), the choice of V_1 was to some extent arbitrary, as we could have added to it several other $Z(3)$ invariant terms with the same dimensions. However, for Z restricted to the minima of V_0 , there are only three independent operators which are gauge invariant, $Z(3)$ invariant, and at most fourth order in the field, for which the three terms we have included in the potential of Eq. (5) are a convenient choice.

The parameters appearing in Eqs. (4)–(5) are available through straightforward calculations in the effective theory, once we demand that the following conditions are met:

- The integration-out of the heavy degrees of freedom in the effective theory produces a theory for the spatial gauge field $\mathbf{A}$ and a traceless hermitian scalar field a , whose leading order Lagrangian density agrees with that of EQCD with the identification $a \leftrightarrow A_0$.
- The leading order tension and width of the effective theory domain wall separating two distinct $Z(3)$ minima agree with the corresponding full theory results.

It was shown in Ref. [1] that to leading order this leads to the results

$$\tilde{c}_1 = T, \quad \tilde{c}_2 = 0.118914, \quad \tilde{c}_3 = \frac{3}{4\pi^2 T}, \quad v = 3.005868T, \quad (7)$$

leaving only two dimensionless numbers corresponding to the ratios of the masses of the heavy excitations undetermined.

3. PHASE DIAGRAM AND NON-PERTURBATIVE TESTS

At high temperatures, *i.e.* deep in the deconfined phase, the perturbative matching performed in Ref. [1] guarantees that new effective theory reproduce the correct long-distance physics of the full one, but close to T_c we need additional non-perturbative matching. Keeping the heavy masses as free parameters for now, we can, however, already make some generic remarks about the properties of the new theory. Tuning the values of these quantities, one can shift the minima of the tree level potential from the three

Figure 1. Preliminary results for the probability density distribution of $\text{tr } \mathcal{Z}$ on a (rotated) complex plane [7]. The value of g_3^2/T is increased from left to right but the heavy mass ratios are kept fixed, which makes the transition from the deconfined to the confining phase clearly visible.

deconfined $Z(3)$ minima to a confining one at $\mathcal{Z} = 0$, which corresponds to a strongly first order phase transition at weak coupling. Increasing the value of g_3 , the fluctuations around the minima are on the other hand enhanced, which we believe will turn the transition to weakly first order. Thus, we expect our theory to be able to mimic the phase transition of the full theory to at least some extent, once its parameters are properly adjusted.

To make the above statements more quantitative and, in particular, to find optimal values for the undetermined parameters, with which the correlation lengths of various observables agree with the full theory ones even near the phase transition, it is necessary to perform non-perturbative lattice simulations with the effective theory Lagrangian. There, the first task should be the mapping of the phase diagram of the new theory in terms of g_3^2/T and the mass ratios, and in particular to the determination of the order of the phase transition line. Work towards this goal is currently being carried out [7].
